A Comparative Study of Crossover Operators for Genetic Algorithms to Solve the Job Shop Scheduling Problem

JORGE MAGALHÃES-MENDES Department of Civil Engineering CIDEM School of Engineering – Polytechnic of Porto Rua Dr. António Bernardino de Almeida, 431 – 4200-072 Porto PORTUGAL jjm@isep.ipp.pt

Abstract: - Genetic algorithms (GA) are wide class of global optimization methods. Many genetic algorithms have been applied to solve combinatorial optimization problems. One of the problems in using genetic algorithms is the choice of crossover operator. The aim of this paper is to show the influence of genetic crossover operators on the performance of a genetic algorithm. The GA is applied to the job shop scheduling problem (JSSP). To achieve this aim an experimental study of a set of crossover operators is presented. The experimental study is based on a decision support system (DSS). To compare the abilities of different crossover operators are tested on a set of standard instances taken from the literature. The makespan is the measure used to evaluate the genetic crossover operators. The main conclusion is that there is a crossover operator having the best average performance on a specific set of solved instances.

Key-Words: - Scheduling, Genetic Algorithms, Crossover Operators, Optimization, Operations Research, JSSP.

1 Introduction and Background

Scheduling is one of the most critical issues in the planning and managing of manufacturing process. The difficulty of finding the optimal schedule depends on the shop environment, the process constrainsts and the performance indicator. One of the most difficult problems in this area is the job shop scheduling problem (JSSP), Qing-dao-er-ji and Wang [38].

The JSSP may be described as follows: given n jobs, each job must be processed on m machines. Each operation uses one of the m machines for a fixed duration. Each machine can process at most one operation at a time and once an operation initiates processing on a given machine it must complete processing on that machine without interruption. A schedule is a complete set of operations ($n \ge m$), to be processed on different machines, in a given order. The problem is to find a schedule of minimal time to complete all jobs.

The JSSP is considered as a particularly hard combinatorial optimization problem, Lawler et al. [10].

Exact methods (Giffler and Thompson [21], Carlier and Pinson [22, 23], Brucker et al. [24], Williamson et al. [25]) have been successful in solving small instances. Problems of dimension 15×15 are still considered to be beyond the reach of today's exact methods.

Many approximate methods have been developed in the last two decades to solve the JSSP, such as:

- 1. *Simulated annealing* (SA) Lourenço [12];
- 2. *Tabu search* (TS) (Nowicki and Smutnicki [9, 31], Pezzela and Merelli [7], Zhang et al. [11, 35]),
- Evolutionary algorithm (EA) techniques like genetic algorithms (GA) - Aarts et al. [15], Croce et al. [17], Dorndorf et al. [18], Wang and Zheng [19], Essafi et al. [3], Gonçalves et al. [4], Hasan et al. [27], Mendes [30], Qing-dao-er-ji and Wang [38], Choi and Park [39], Chiu et al. [40, 41]);
- 4. EA related techniques like *particle swarm optimization* (PSO) Sha and Hsu [6];
- 5. *Greedy randomized adaptive search procedure* (GRASP) Aiex et al. [16] and Binato et al. [20];
- 6. Others metaheuristics Rego and Duarte [8] proposed a filter-and-fan approach based on the *shifting bottleneck procedure* (SBP) and Pardalos et al. [32].

Evolutionary algorithms often perform well approximating solutions to all types of problems. The most popular type of EA is the GA. The GA seeks the solution of a problem in the form of strings of numbers (traditionally binary, although the best representations are usually those that reflect something about the problem being solved), by applying operators such as crossover and mutation.

The performance of a GA is dependent on the genetic operators in general and on the type of crossover operator, in particular. During the evolution process by a GA, if the selected chromosomes are identical, some of the crossover operators have failed to create offspring that are different from their parents. Effective crossover in a GA is achieved through establishing the optimum relationship between the crossover and the search problem itself [28].

Some literature focuses on the genetic operators, e.g., Sywerda [33] and De Jong and Spears [34] compared the various crossover operators, particularly the numbers of crossover points. A relevant result is that sometimes the final output would be better if the number of crossover points was increased.

Besides empirical analysis, substantial efforts have been invested in comparing, from theoretical perspectives, between mutation and crossover as well as between the various crossover operators [34]. However, these theories are not general enough to allow for predicting when to apply or what type of crossover operator to employ [28].

Given the current state of knowledge is justified, therefore, additional research work that allows to obtain new results.

This paper describes an experimental study of a set of genetic crossover operators. These crossover operators are applied on a hybrid genetic algorithm. This hybrid genetic algorithm works with a local search using the Monte Carlo method [30]. The aim of this study was to validate empirically the most appropriate crossover operator for solving the job shop scheduling problem.

The remainder of the paper is organized as follows. In section 2 is defined the problem. In section 3 is referred the decision support system. In section 4 we refer the advantages of using genetic algorithms in combinatorial nature problems.

In section 5 is described the genetic algorithm. In section 6 are presented and discussed the results of the experimental study. Finally, conclusion and remarks for further works are given in Section 7.

2 Problem Definition

There are a set of jobs $J = \{1, ..., n\}$, a set of machines $M = \{1, ..., m\}$, and a set of operations O =

 $\{o_0, o_1, ..., o_{ji}, ..., o_{nm}, o_{nm+1}\}$. Set *O* contains all the operations of each job. Each job has *m* operations. Each machine can process at most one operation at time.

The JSSP is to find a schedule which minimizes the makespan (C_{max}), that is, the finish time of the last operation completed in the schedule, taking into account the precedence constraints.

Let $O = \{o_0, o_1, ..., o_{ji}, ..., o_{nm}, o_{nm+1}\}$ denote the set of all operations $(n \ge m)$ to be scheduled and $M = \{1,..., m\}$ the set of machines. The operations o_0 and o_{nm+1} are dummy, have no duration and represent the initial and final operations. The operations are interrelated by two kinds of constraints:

- First, the precedence constraints, which force each operation o_{ji} to be scheduled after all predecessor operations are completed P_{ji} ;
- Second, operation o_{ji} can only be scheduled if the machine it requires is idle. Further, let d_{ji} denote the (fixed) duration (processing time) of operation o_{ji}.

Let F_{ji} represent the finish time of operation o_{ji} . A schedule can be represented by a vector of finish times $(F_{11,.}, F_{ji}, ..., F_{nm+1})$.

Let A(t) be the set of operations being processed at time t, and let $\mathbf{r}_{ji} = 1$ if operation o_{ji} requires machine m to be processed and $\mathbf{r}_{ji} = 0$ otherwise.

The conceptual model of the JSSP can be described the following way:

$$\mathbf{Min} \ \mathbf{F}_{nm+1} \tag{1}$$

subject to:

$$F_{kl} \leq F_{ji} - d_{ji} \qquad j = 1, \dots, n \; ; \; i = 1, \dots, m \; ; \; kl \in P_{ji} \quad (2)$$

$$\sum_{ji\in A(t)} r_{ji} \le 1 \qquad i\in M \ ; \ t\ge 0 \tag{3}$$

$$F_{ji} \ge 0$$
 $j = 1,...,n$; $i = 1,...,m$ (4)

The objective function (1) minimizes the finish time of operation o_{nm+1} (the last operation), and therefore minimizes the *makespan*. Constraints (2) impose the precedence relations between operations and constraints (3) state that one machine can only process one operation at a time. Finally (4) forces the finish times to be non-negative.

3 A decision support system (DSS)

A DSS combines a genetic algorithm, a schedule generator scheme (SGS) and a local search procedure, consisting in the following steps, see Figure 1:

• **Step1**: Combines a genetic algorithm with a schedule generation scheme

(SGS). This SGS generates parameterized active schedules. This step allows to obtain a schedule for each chromosome;

• **Step2**: This step makes use of a local search procedure that attempts to improve the solution obtained previously.

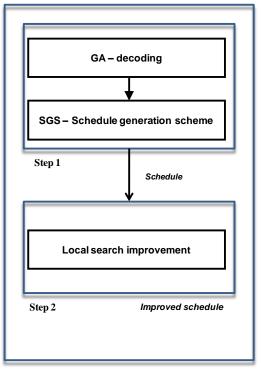

Fig.1 – Architecture of the approach.

The DSS allows the user choose the crossover operator:

- GA-MC-SPc: Single-Point crossover or simple crossover;
- GA-MC-TPc: Two-Point crossover;
- GA-MC-Uc: Uniform crossover or discrete crossover;
- GA-MC-Fc: Flat crossover.

The DSS was developed using the Visual Basic for Applications (VBA) from Microsoft and the Gantt Time Package V3.21 [30].

4 Real-coded evolutionary algorithms

The evolutionary algorithms are an interdisciplinary research area comprising several paradigms inspired by Darwinian principle of evolution.

The current stage of research considers, among others, the following paradigms: genetic algorithms,

genetic programming, evolutionary strategies, neuroevolution and differential evolution.

The genetic algorithms have been applied successfully in several areas, such as bioinformatics, computational science, engineering, economics, chemistry, manufacturing, mathematics and physics.

A real-coded GA is adopted in this article. Compared with the binary-code GA, the real-coded GA has several distinct advantages, which can be summarized as follows, Y.-Z. Luo et al. [36]:

- It is more convenient for the real-coded GA to denote large scale numbers and search in large scope, and thus the computation complexity is amended and the computation efficiency is improved;
- The solution precision of the real-coded GA is much higher than that of the binary-coded GA;
- As the design variables are coded by floating numbers in classical optimization algorithms, the real-coded GA is more convenient for combination with classical optimization algorithms.

5 Genetic Algorithms

Genetic algorithms (GA) are search algorithms based on the mechanics of natural selection and natural genetics. They combine survival of the fittest among string structures with a structured yet randomized information exchange to form a search algorithm with some of the innovative flair of human search [1].

The general schema of GA may be illustrated as follows (Fig. 2).

```
procedure GENETIC-ALGORITHM

Generate initial population P_0;

Evaluate population P_0;

Initialize generation counter g \leftarrow 0;

While stopping criteria not satisfied repeat

Select some elements from Pg to copy into Pg+1;

Crossover some elements of Pg and put into Pg+1;

Mutate some elements of Pg and put into Pg+1;

Evaluate some elements of Pg and put into Pg+1;

Increment generation counter: g \leftarrow g+1;

End while

End GENETIC-ALGORITHM;

Fig.2 - Pseudo-code of a genetic algorithm.
```

First of all, an initial population of potential solutions (individuals) is generated randomly. A selection procedure based on a fitness function enables to choose the individuals candidate for reproduction. The reproduction consists in recombining two individuals by the crossover operator, possibly followed by a mutation of the offspring. Therefore, from the initial population a new generation is obtained. From this new generation, a second new generation is produced by the same process and so on. The stop criterion is normally based on the number of generations.

5.1 Decoding

The genetic algorithm uses a random key alphabet which is comprised of real random numbers between 0 and 1.

A chromosome represents a solution to the problem and is encoded as a vector of random keys (random numbers).

Each solution chromosome is made of 2n genes where *n* is the number of operations:

Chromosome = $(gene_1, ..., gene_n, gene_{n+1}, ..., gene_{2n})$

The first half $(gene_l, ..., gene_n)$ corresponds to the potential solution to the optimization problem, that is, one gene for each activity. The second half $(gene_{n+1}, ..., gene2_n)$ defines the vector where each gene has an associated delay time.

The priority decoding expression used the following expression:

$$\begin{aligned} & PRIORITY_{j} = gene_{j} \\ & Delay_{j} = gene_{n+j} \times 1.5 \times mdur, \qquad j = 1, \dots, n. \end{aligned}$$

where *mdur* is the maximum duration of all operations. The factor 1.5 was chosen as a result of a careful fine-tuning experimental phase.

5.2 Initial population

The initial populations are generated randomly. The quality of this population is poor and one way to improve it is to incorporate some chromosomes generated by priority rules.

In this paper are selected the priority rules GRPW (greatest rank positional weight) and SPT (shortest processing time) to improve some chromosomes of the initial population.

5.3 Crossover operators

The genetic algorithms typically use the following types of operators:

- **Selection**: Operator for selecting individuals for reproduction according to their fitness;
- **Crossover** (Sexual Recombination): Operator of merging the genetic information of two individuals. In many respects the

effectiveness of crossover is depended on coding;

• **Mutation** (Asexual): In real evolution, the genetic material can by changed randomly by erroneous reproduction or other deformations of genes, e.g. by gamma radiation. In genetic algorithms, mutation realized as a random deformation of alleles with a certain probability, Shaparov [37].

Usually, there are two means of modifying genetic material: a recombination operation that could be understood as some kind of crossover and mutation.

In this study we compared the following crossover operators:

- Single-point Crossover or simple crossover;
- Two-point Crossover;
- Uniform Crossover or discrete crossover;
- Flat Crossover.

The reasons by which these crossover operators were chosen are:

- Single-point crossover: is a simple and oftenused method for genetic algorithms;
- N-point crossover. Instead of only one, N breaking points are chosen randomly. Every second section is swapped. Among this class, two-point crossover is particularly important;
- Usually flat or discrete crossovers are applied in real-coded genetic algorithm (Shaparov [37]).

5.3.1 Single-point crossover

After reproduction, crossover may proceed in two steps. First, members of the newly reproduced chromosomes in the mating pool are mated at random. Second, each pair of chromosomes undergoes crossover as follows: an integer position kalong the chromosome is selected uniformly at random between 1 and the chromosome length l. Two new chromosomes are created swapping all the genes between k+1 and l [1], see Fig. 3.

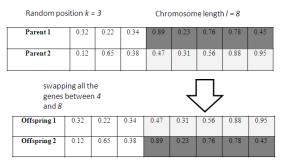

Fig.3 – Single-point crossover operator example.

5.3.2 Two-point crossover

Two-point crossover is very similar to single-point crossover except that two cut-points are randomly generated instead of one, see Fig. 4.

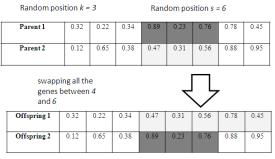

Fig.4 – Two-point crossover operator example.

5.3.3 Uniform crossover

In uniform crossover, a value of the first parent's gene is assigned to the first offspring and the value of the second parent's gene is to the second offspring with a probability value p_c .

With probability p_c the value of the first parent's gene is assigned to the second offspring and the value of the second parent's gene is assigned to the first offspring, see Fig. 5.

Parent 1	0.32	0.22	0.34	0.89	0.23	0.76	0.78	0.45

Offspring 2	0.12	0.65	0.38	0.47	0.31	0.56	0.88	0.95

Fig.5 – Uniform crossover operator example.

This work used a probability p_c of 0.7. An example of this operator has been used successfully in Gonçalves et al. [4].

5.3.4 Flat crossover

Consider the following parents:

 $Parent1 = (x_{1,1}, ..., x_{1,n})$ $Parent2 = (x_{2,1}, ..., x_{2,n})$

and a vector of random values $\mathbf{r} = (\mathbf{r}_1, \ldots, \mathbf{r}_n)$.

The offspring $1 = (x_{1}^{1}, ..., x_{n}^{1})$ is computed as a vector of linear combinations in the following way (for all i = 1, ..., n):

$$\boldsymbol{x}_{i}^{1} = \boldsymbol{r}_{i} \, \boldsymbol{x}_{1,i} + (1 - \boldsymbol{r}_{i}) \, \boldsymbol{x}_{2,i} \quad , \qquad \boldsymbol{i} = 1, \dots, \boldsymbol{n}$$
(5)

Second offspring is computed analogously, see Fig.6.

Fig.6 – Flat crossover operator example.

5.4 Random mutation

The mutation operator preserves diversification in the search. The mutation operator chosen was the random mutation. This operator is applied to each offspring in the population with a predetermined probability. For a randomly chosen gene *i* of an individual (*gene*₁, ..., *gene*_n, *gene*_{n+1}, ..., *gene*_{2n}), the allele *gene*_i is replaced by a randomly chosen value from a interval]0, 1[.

We assume that the probability of the mutation in this work is 0.1%. With 1000 genes positions we should expect $1000 \ge 0.001 = 1$ genes to undergo mutation for this probability value.

5.5 Configuration of the experiments

All results reported for GA-MC were obtained with the same parameters. Though there is no straightforward way to configure the parameters of a genetic algorithm, we obtained good results with values:

- **Population size:** 2 × number of operations for each problem;
- **Initial population**: 1% chromosomes calculated by priority rules GRPW and SPT;
- **Top** (best): 1% from the previous population chromosomes are copied to the next generation;
- Mutation rate: 0.1%;
- **Termination criterion:** Maximum number of generations.

5.6 Evolutionary strategy

To breed good solutions, the random key vector population is operated upon by a genetic algorithm.

There are many variations of genetic algorithms obtained by altering the reproduction, crossover, and mutation operators.

Reproduction is a process in which individual (chromosome) is copied according to their fitness values (*makespan*).

Reproduction is accomplished by first copying some of the best individuals from one generation to the next, in what is called an elitist strategy.

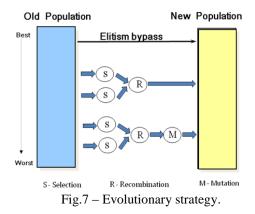

In this paper the fitness proportionate selection, also known as roulette-wheel selection, is the genetic operator for selecting potentially useful solutions for reproduction. The characteristic of the roulette wheel selection is stochastic sampling.

The fitness value is used to associate a probability of selection with each individual chromosome. If f_i is the fitness of individual *i* in the population, its probability of being selected is,

$$\boldsymbol{p}_i = \frac{f_i}{\sum\limits_{i=1}^N f_i} \quad , \qquad i = 1, \dots, \boldsymbol{n} \tag{6}$$

A roulette wheel model is established to represent the survival probabilities for all the individuals in the population.

Fig. 7 shows this evolutionary strategy with the operators selection, recombination (or crossover) and mutation.

This evolutionary strategy was applied to the resource constrained project scheduling problem with a good performance, see Mendes [2, 26].

6 Numerical experiments

To evaluate the performance of each crossover operator, we considered the following classes of problems, taken from the literature:

• ABZ5, ABZ6, ABZ7, ABZ8 and ABZ9 proposed by Adams et al. [10];

- FT6, FT 10 and FT20 originally proposed by Fisher and Thompson [13];
- LA1-LA40 proposed by Lawrence [14];
- ORB1-ORB10, proposed by Applegate and Cook [29].

Tables 1, 2, 3 and 4 summarize the experimental results. It lists number of jobs, number of operations, instance, best known solution (BKS), GA-MC-SPc, GA-MC-TPc, GA-MC-Uc and GA-MC-Fc. The last row of each table shows the value of the Average Relative Deviation (ARD).

The ARD is calculated in the following way:

$$RE = \sum_{i=1}^{NS} \frac{C_{\max_i} - BKS_i}{BKS_i}$$
(7)

$$ARD = \frac{RE}{NIS}$$
(8)

where NIS is number of instances solved.

Problem	BKS	GA-MC- SPc	GA-MC- TPc	GA-MC- Uc	GA-MC- Fc
ABZ5 (10 x 10)	1234	1234	1234	1234	1234
ABZ6 (10 x 10)	943	943	943	943	943
ABZ7 (15 x 20)	656	688	695	690	693
ABZ8 (15 x 20)	645	704	708	702	701
ABZ9 (15 x 20)	661	715	720	724	721
% ARD		4,44%	4,93%	4,71%	4,68%

Table 1: Experimental results for instances ABZ5-ABZ9.

Problem	BKS	GA-MC-	GA-MC-	GA-MC-	GA-MC-
		SPc	ТРс	Uc	Fc
FT06 (6 x 6)	55	55	55	55	55
FT10 (10 x 10)	930	930	930	930	930
FT20 (20 x 5)	1165	1165	1165	1165	1165
% ARD		0,00%	0,00%	0,00%	0,00%

Table 2: Experimental results for instances FT06, FT10 and FT20.

In most of the problems, the single crossover operator performs better than the others and is the operator with lowest ARD, see Tables 1, 2, 3, 4 and 5.

Unlike the algorithm GA-MC-SPc that always has the best ARD, the algorithm GA-MC-SPc has not always the second best (lowest) ARD. Indeed, the algorithm GA-MC-Fc for ABZ problems (Table 1) obtains the second lowest ARD.

This result can lead to considerer that the operator Fc is second best for larger problems, i.e.,

problems greater than 10x10. For problems larger than 10x10, we obtain the following values of ARD: 1.51% (GA-MC-SPc), 1.89% (GA-MC-TPc), 1.84% (GA-MC-Uc) and 2.13% (GA-MC-Fc), see Table 5.

Globally the second best value for the ARD is obtained by algorithm GA-MC-Uc and the third best value by the algorithm GA-MC-TPc, see Table 6.

With these results, for these types of problems, the single-crossover performed the best results, followed by the uniform crossover operator.

% ARD	1222	0,31%	0,47%	0,47%	0,64%

Table 3: Experimental results for instances LA01-LA40.

Tables 1, 2, 3 and 4 shows that the GA-MC-SPc is able to find the best know solution for 2 instances in the set ABZ (40%), 3 instances in the set FT (100%), 28 in the set LA (70%) and 9 in the set of ORB (90%).

We must think why the SPc operator shows better results. A strong possibility relates to the theory of *building blocks* (Goldberg [1]). This operator has only a cut, so it is more likely to not destroy blocks. Instead, the operator of two points cut large blocks and operator's uniform and flat ignores its existence.

This can be a very important result in choosing the crossover operator when using genetic algorithms, particularly in job shop.

Table 5: Average relative deviation for problems greater than 10x10.

Additionally, the GA-MC-SPc results are compared against the most recent work in the literature.

The performance of GA-MC-SPc was evaluated on a standard set of 50 benchmark instances belonging to two classical sets known LA from Lawrence [14] and ORB from Applegate and Cook [29].

	-					

Table 6: Average relative deviation with all problems.

As different authors used different number of problems, the comparison is based only on those problems that authors considered. Note that the authors have different approaches to solve the JSSP problem.

We compare the obtained results with the aforementioned state of art approaches:

- Qing-dao-er-ji and Wang [38];
- Rego and Duarte [8];
- Hasan et al. [27];
- Gonçalves et al. [4];
- Aarts et al. [15];
- Dorndorf et al. [18];
- Binato et al. [20];
- Nowicki and Smutnicki [31];
- Sha and Hsu [6];
- Pardalos et al. [32];
- Adams et al. [10];
- Zhang et al. [35].

The result is showed in Table 7.

The algorithm GA-MC-SPc gives good results when compared to the state of art. In Table 7 we can see that the algorithm proposed is among the top ten best performing.

This study limited the number of generations for all operators tested. The number of generations was limited to 400. A higher number of generations for all operators would increase the computational time. Although there is convergence of the algorithms close to 400 generations, an increase of generations in the proposed algorithm can improve its global performance.

The experiments were performed on an Intel Core 2 Duo CPU T7250 @2.00 GHz. The computational times dispended are in the range [7, 3100] seconds.

Table 7: Comparison of the % deviations for the different number of problems authors considered. This paper presents an experimental study of a set of crossover operators, namely single-crossover, twopoint crossover, uniform crossover and flat crossover. The single-crossover has the best results, followed by the uniform crossover operator.

This can be a very important result in choosing the crossover operator when using genetic algorithms, particularly in job shop.

Additionally, the best crossover operator was tested on a set of 50 standard instances taken from the literature and compared with the best state-of-the-art approaches. The algorithm produced good results when compared with other approaches.

Although there is convergence of the algorithms close to 400 generations, an increase of generations in the proposed algorithm (GA-MC-SPc) can improve its global performance.

Further work could be conducted to explore the possibility of genetically correct the chromosomes supplied by the genetic algorithm to reflect the solutions obtained by the local search heuristic.
