Abstract: - The paper herein considers the study of convective heat transfer in flat plate solar collectors, as it is seen from the analysis on research of the heat transfer by a circular and flat tubes upon conforming the forced and free convections, placed vertically or horizontally with various liquid flow directions. There have been obtained Nusselt criterion dependencies in circular and flat pipes, which shows that corresponding equations allow defining the heat transfer intensity for all fluids with appropriate accuracy. As well there has been studied Prandtl criterion for fluids, which plays an important role in points spacing as regard to the curve. In each case the lines are with a tip 1/3, as in the research herein only the laminar conditions have been considered. The article herein considers the pilot tests based on tubular solar collectors with an absorbing shield. The aim of the experiment thereof is the research of thermal properties of tubular solar collector for producing hot water.

Key-Words: - Flat plate solar collector, convection, convective heat transfer, solar radiation

1 Introduction

To control and design many thermal systems it is necessary to specify heat transfer coefficients between a solid body and liquid [1], for instance, for solar collectors. Indeed, such thermal systems are always subject to temporal changes of some thermal parameters (solar thermal flow, liquid or solid substance temperature).

Therefore the heat transfer coefficient in the solid fluid medium cannot be considered as constant. Here is being investigated the problem of conjugated heat transfer [2]. In this case the heat transmission effect in the solid wall can’t be neglected. If conjugated facts are neglected the temperature or thermal flow are under boundary conditions. However, in practice both the temperature and thermal flow on the solid body are defined simultaneously, which are linked with dynamic and energy equations [3].

It is known, that upon convective heat transfer computation according to experimental data, the effects of such heat transfer phenomena might be neglected, corresponding Nusselt numbers, as a rule, will be underestimated [4-6].

Recently, numerical methods have been applied to several researches [7-10]. Effect of bound conductive-convective flows in channels has been studied too in [11,12], with regular changes of temperature boundary conditions (temperature or thermal flow) or flow velocity. In the studies thereof it has been shown that thermal diffusion characteristic times in the solid body and fluid are the parameters dominating in the bound heat transfer. There were carried out several researches dealing with the problems of the transition process heat transfer factors in the flat plates for various boundary conditions. Rebay & al. [13] submitted measurements of convective heat transfer local coefficients between the uniformly heated plate and air flow. Rebay & al. [14] studied unsteady forced convective flow heat transfer along a flat plate with a sharp change of thermal flow density on the surface without constant pressure along the flow direction.

Forced convection from microstructure on the flat plate has been investigated by Rebay & al. [15]. In [15] there has been studied the boundary layer longitudinal conductivity. Differential method has been used to decrease differential equations with partial derivatives for ordinary differential ones, which are solved computationally by means of computer technology. Mladin & al. [16] simulated unsteady thermal boundary layer, being developed along the plate’s finite thickness upon temperature change in the lower plate surface ramp. To simulate transient heat transfer there were applied athenmatical approaches: integral method based on the methodology of Carman- Pohlhausen equations system’s NavierStokes complete equation. Both
methods were in the mode of stationary state, numerical methods showed that both techniques are in line for 5% at steady condition and 2,6% at transient state. In the present work there has been used purely numerical method for studying the unsteady laminar convection on the flat plate with different thickness subjected to the surface temporal change.

2 Method of research

2.1 Pilot tests of solar-driven installation

The goal of the current experiment is heating medium temperature determination in the heat absorber’s heat removing channel.

Testing device is installed at the area latitude $\Psi =43^\circ$, and the solar collectors slope angles equal to $55^\circ$, $45^\circ$, $30^\circ$ in the circumanian cycle of Kazakhstan, Almaty city.

Solar electric installation consists of accumulator box, solar collector, electric heater, support frame.

Accumulation tank has a heat-insulated cylinder case with a connecting branch for hot water intake and heat sealed stub-pipes for connecting the solar collectors.

On the tank cover there is a connecting branch for air outlet upon the system filling up.

Between the tank body and a case there is thermal insulation. At the tank bottom there mounted the pillars for fixing to the support. In the tank’s lower part there installed an electric heating unit (EHU). Solar collector consists of black polyethylene tubes register with honeycomb insulation, lined out from above and below with pods (hydraulic collector), at that, the tubes length constitutes no less than 2,5 meters. Collector specific character is in the fact, that boundary tubes are manufactured from metal, and they allow regulating the thin-wall tubes strain, whereby enhancing stiffness of the tubular solar collector in the solar radiation absorption plane and excluding «housing unit».

To carry out the test at the solar site there is mounted SU (SI)-500 with tubular solar collectors. Tests have been conducted in the following mode: accumulator box (BA) was filled in with water at 9 am through a liquid level, i.e. filling in is an automatic process. Throughout the day there is water withdrawal from the accumulator tank. In the end of the working day – 5pm the water from accumulator tank is discharged completely.

2.2 Technical characteristics of solar collector

To determine the installation technical and operational characteristics there has been conducted temperature sensor readings recording. As temperature sensors there were used chromel-copel thermocouples to measure the temperature in 6 installation’s points. Thermocouples readings recording has been fulfilled with an automatic recorder KCP-4. In parallel with thermocouples in a number of points there were installed mercury-filled thermometers for check measurements.

Following values were continuously recorded during the tests:
- flow density of the total solar radiation on the $E$ collector surface;
- outside air temperature $t_3$;
- wind speed in unperturbed flow $v$;
- cold tap water temperature $t_3$;
- water temperature at the solar collector input and output $t_1$, $t_2$;
- water temperature in an accumulator box in three sections along the box height at a distance of 0,1, 0,3 and 0,4 m from the bottom $t_5$, $t_6$, $t_7$;
- temperature of the water, released to a consumer $t_8$;
- water discharge in the flow circuit $G$.

Measurements of all above mentioned parameters have been conducted every hour dawn-to-dusk starting from 9 am. Proceeding from measurement results there have been determined average total solar radiation flux density values during the tests on the $E$ collector surface, outside air temperature $t_3$, wind speed $v$, water temperature at the collectors system input $t_1$ and output $t_2$. Those values were found through planimetering the squares, limited with curves $x(\tau)$, where $x$- is any of the denoted above values in the time range of the test conducting. Further there was computed thermal performance of the solar installation:

$$ Q = G \cdot c_1 \cdot (t_2 - t_1) \cdot \tau + \Delta Q_1 $$

where $\tau$-testing time; $\Delta Q_1$-heat, accumulated in-line by the experiment completion, which, as a rule, has not exceeded 0,05 and $\eta$ is the solar installation daily performance

$$ \eta = \frac{Q}{\sum E \cdot \sum S} $$

where $\sum E = \bar{E} \cdot \tau$ is the total amount of the sum solar radiation incident during the time $\tau$ on 1 m2 on the solar collector surface and $\sum S$ is an overall square of the solar collectors heat absorption areas.
Tests outcomes for SU (SC)-500 with a tubular solar collector are listed in the table 1. Meteorological parameters average values constituted in the tests: $E=375-888$ Wt/m²; $t=14-20\degree C; \nu=1,0-4,5$ m/sec, a water flow in water-flow circuit changed within $73,1-157,5$ kg/hour. Consequently there has been received wide range of performance values from 0,2 to 0,64. Results of tests under usage of $G=2-3$ kg/sec. is approximated with linear dependence

$$\eta=0,782-11,3(\Delta \bar{t}/E)$$

Solar collector experimental findings thereof and computational fluctuations cannot be explained with experimental errors. It may be shown, that upon parameter calculation $\Delta \bar{t}/E$ directly on the water temperature at the outlet from the collector, all experimental points, corresponding to the run-off $G=2-3$ kg/sec., inclusive, in actual fact are on the one straight line.

As an example the figures 1 and 2 present the installation test results. During the test (from 9.00 to 17.00) a consumer received 0,5m³ of water with temperature about 50°C. There is defined the water temperature distribution along the accumulation tank height. That data illustrates well the water stratification extent in the tank. Temperature difference in the upper and lower strata amounted at the midday to 10-15°C.

Heat loss high level is conditioned by the fact, that the system’s connecting pipelines total is about 5m and due to poor heat insulation, i.e., instead of polyurethane insulation there was used foam insulation.

2.3 Results of water temperature change upon different water volume

Figures 1-7 present the results of water temperature change upon different water volume. The most optimal is the tank volume of 70-100 l per one square meter. With volume increase the water temperature in the tank lowers, for example, for 250 l–55-57°C, 300 l–50-53°C, 400 l–46-48°C, 500 l-45-47°C.

According to the known data, at the latitude less than 54° there applied 90% of simple single circuit solar installation without a stand-by with natural circulation circuit for hot water supply of seasonal heat consumers.

In flat plate solar collectors heat absorption area and working liquid conditions are not favorable enough, particularly, when the heat receiver (boiler) is placed horizontally. Actually, the liquid motion speed is low here and it is heated from top, and, as a result, convective currents mixing the liquid do not develop. At the boiler’s sloping position under known conditions there might happen the natural convection improving the heat transfer.

Task solution of heat transfer between radiant heat absorbing surface and power liquid flat heaters upon applying the forced and natural convection (first type boundary conditions) presents sufficient difficulties. In case of applying the natural convection to the forced flow the velocity gradient on the wall will depend on the interrelated parameter part, defining both forced and free flow. In that case velocity gradient \( A = \left( \frac{dW}{dy} \right)_{y=0} \) is not known in advance (for circular tube) \( A = \rho \bar{W}/d \), for flat one \( A = 6\bar{W}/h \), \( (A) \) can be defined from the motion equation.

Let us use the motion equation in a simplified form, omitting inertial terms, but taking into account the upward force. Supposing the liquid physical properties being constant and presenting the density in the form of linear temperature, we will obtain:

\[
\frac{\partial^2 W_x}{\partial y^2} + \frac{g\beta (t_c - t_0)}{v} + \frac{1}{\mu} \frac{\partial P}{\partial x} = 0 \tag{1}
\]

where \( \beta \)- volume coefficient; \( t_0 \)- flow temperature far from the wall, admitted as equal to the inlet temperature, as within the thermal initial section the temperature in the flow core changes ineffectually.

The equation for temperature distribution is given by:

\[
t - t_c = \frac{\int_0^\eta e^{-\eta^3}d\eta}{\int_0^{t_0} e^{-\eta^3}d\eta} \tag{2}
\]

where \( t_c \)- wall temperature, \( \eta = \left( \frac{A}{g\delta x} \right)^{1/3} y \)- new independent variable. Denominator (2) represents the gamma function, the values of which are tabulated:

\[
\int_0^\infty e^{-\eta^3}d\eta = \Gamma \left( \frac{3}{4} \right) = 0,8930 \tag{3}
\]

Having substituted in (1) the value from (2) and upon integrating it we can define \( A = \left( \frac{dW}{dy} \right)_{y=0} \). To carry out integration we approximate (2) and reduce the equation as follows:

\[
\frac{t - t_c}{t_c - t_0} = 1 + b_1 e^{-\eta} + b_2 e^{-2\eta} + b_3 e^{-3\eta} \tag{4}
\]

which meets boundary conditions and upon the constants appropriate selection conforms quite well with (1). Having inserted \( t_c - t_0 \) from (4) into (1), we find
\[
\frac{\partial^2 W_x}{\partial y^2} = \frac{g\beta(t_c - t_0)}{v} (1 + b_1 e^{-\eta} + b_2 e^{-2\eta}) + b_3 e^{-3\eta}) - D \tag{5}
\]

where \( D = \frac{1}{\mu} \frac{\partial p}{\partial x} \approx \text{const} \).

Boundary conditions are in the following form:

\[ x = 0, \quad t = t_0 \]

\[ W_x = 6W \left( \frac{Y}{h} - \frac{Y^2}{h^2} \right), \quad W_x = 8W \left( \frac{Y}{a} - \frac{Y^2}{d^2} \right) \tag{6} \]

The first equation is for flat, the second – for circular tube. Having executed integration and used boundary conditions we obtain the expression for non-dimensional velocity speed on the wall. For a flat tube

\[ \varphi = \frac{Ah^2}{v} = 6Re + 0.43Gr \left( \frac{gx}{Pr\rho h} \right)^{1/3} \tag{7} \]

\[ Re = \frac{\bar{W}h}{v}; \quad Gr = \frac{g\beta(t_c - t_0)h^3}{v^2} \]

Unfortunately, the expression thereof contains non evident \( \varphi \). Therefore in (7) it was substituted with an approximate relationship:

\[ \varphi = 6Re + 0.92 \frac{Gr^{3/4}}{Pr^{1/4}} \left( \frac{\alpha}{h} \right)^{1/4} \tag{8} \]

As you can see, the initial supposition about \( \varphi \) (or \( \bar{A} \)) consistency is not justified. However, \( \varphi \) changes in length relatively ineffectually (\( \varphi \sim x^{-1/4} \)). Therefore, it will not be a great mistake if to use an average value in the section with the length:

\[ \bar{A} = \frac{Ah^2}{v} 6Re + 0.736 \frac{Gr^{3/4}}{Pr^{1/4}} \left( \frac{\alpha}{h} \right)^{1/4} \tag{9} \]

Let’s define now local heat-transfer coefficient, assigning it to the difference between the wall temperature and liquid temperature at the inlet to the heating area. Such definition technique (\( \alpha \)) is convenient hereby, as at small values \( \frac{1}{Pe \frac{d}{a}} \) the liquid average mass temperature changes weakly in length

\[ \alpha_0 = \frac{g_c}{t_c - t_0} = \frac{\lambda}{t_c - t_0} \left( \frac{dt}{dy} \right)_{y=0} \tag{10} \]

Having used the correlation obtained previously, we find:

\[ \left( \frac{dt}{dy} \right)_{y=0} = \left( \frac{A}{gax} \right)^{1/3} \frac{\left( \frac{dt}{dy} \right)_{y=0}}{\eta=0} = \left( \frac{A}{gax} \right)^{1/3} \left( \frac{t_c - t_0}{0.893} \right) \tag{11} \]

consequently \( \alpha_0 \) from (8) and (9)

\[ \alpha_0 = \frac{\lambda}{0.893} \left( \frac{A}{gax} \right)^{1/3} \tag{12} \]

Having substituted the value \( A \) from (10) in (11) we find the expression of Nusselt criterion for flow in a flat tube:

\[ Nu = 1.676 \sqrt{Pe} \frac{h}{l} + 0.123 \left( GrPr \frac{h^3}{l} \right)^{3/4} \tag{13} \]

Where \( Nu = \frac{\alpha d}{\lambda}; \quad Pe = \frac{\bar{W} d}{a}; \quad Gr = \frac{g\beta(t_c - t_0)d^3}{v^2} \)

In case of flow in a circular tube the similar analysis brings to an expression:

\[ Nu = 1.615 \sqrt{Pe} \frac{h}{l} + 0.092 \left( GrPr \frac{h^3}{l} \right)^{3/4} \tag{14} \]

where \( NU = \frac{\alpha d}{\lambda}; \quad Pe = \frac{\bar{W} d}{a}; \quad Gr = \frac{g\beta(t_c - t_0)d^3}{v^2} \)

Heat transfer coefficient in (11) and (12) has been assigned to the initial temperature driving force \( t_c - t_0 \).

Fig. 8 Nusselt criterion for liquid flow in flat tube

Upon specifying the coefficient of heat transfer from the heating area to the heated water the thermal flow is defined according to the flow rate and temperature difference of the water being
heated at outlet and inlet. Water temperature is specified at outlet and inlet and the surface temperature through thermocouples readings average.

Experiments have been carried out at the heat transfer surface’s obliquing angles $\phi=30^\circ, 35^\circ, 40^\circ$.

At that, the number $Re=150-500$, i.e., the experiments have been executed mainly at water flow laminar regime. As a determining temperature there has been accepted the water temperature and as a characteristic dimension – the channel equivalent diameter $d=4f/S$. Accepted in the model dimension $d$ secures its geometric similarity to experimental flat solar collectors.

In the result, experimental data in the dependency form $Nu=f(Pld/l)$ and $Nu/Pr^{0.44}=f(Re)$ is given in the Figure 8.

Figures 9,10,11 show, that Prandtl number for the liquid plays an important role in the points spacing as regard to the curve. In all cases the lines are with a slope 1/3, as in the research herein we have considered only laminar mode.

Fig. 9 Nusselt criterion dependence on Reynolds criterion for liquid flow in the flat solar collector

Fig. 10 Nusselt criterion dependence on Reynolds criterion for liquid flow in the flat solar collector

Fig. 11 Dependence of Nusselt-Prandtl criterion on Reynolds criterion for the liquid flow in the flat plate solar collector

Obtained semiempirical formula allowing, in concept, processing and summarizing accumulated experimental data on the heat transfer upon convective heat transfer in the flat plate solar collectors as well gives a possibility to compare the results of theoretical investigations of heat transfer characteristics to experimental data.

Experimental data on heat transfer upon the mutual action of the forced and free convection can be broken down into three groups in compliance with the three main types of flow:

a) flow in vertical tubes bottom-up at heating and top-bottom at cooling;

b) flow in horizontal tubes at heating and cooling;

v) flow in vertical tubes top-bottom at heating and bottom-up at cooling.

In the first case the forced and free convections at the wall match in direction, in the second case they are directed mutually perpendicular, in the third - opposite.

For the cases thereof there have been obtained corresponding equations, which allow defining the heat transfer intensity for all liquids with an
appropriate accuracy. Heat exchange conditions and experimental collected data of the researches thereof are given in the Table 2.

As it is seen from the above mentioned works analysis on studying the heat transfer with circular and flat tubes upon the forced and free convection conformity, ours and foreign researches have been conducted only with the tubes placed vertically or horizontally with different fluid flow directions.

4 Conclusion

Obtained semiempiric formulae, which allow, in principle, processing and generalizing accumulated experimental data on heat transfer at convective heat transfer in flat plate solar collectors, as well they give a possibility to compare the theoretical researches outcomes of various heat transfer characteristics to experimental data.

This work is supported by grant from the Ministry of Education and Science of the Republic of Kazakhstan within the framework of the Project "BR05236693 "Mathematical and computer models, hardware and software tools and experimental development on creation of network combined effective dual-circuit solar collectors with thermosiphon circulation and monitoring of their functioning".
