Abstract—If a robot does not know where it is, it can be difficult to determine what to do next. In order to localize itself, a robot has access to relative and absolute measurements giving the robot feedback about its driving actions and the situation of the environment around the robot. Given this information, the robot has to determine its location as accurately as possible. What makes this difficult is the existence of uncertainty in both the driving and the sensing of the robot. The uncertain information needs to be combined in an optimal way. The Kalman Filter is a technique from estimation theory that combines the information of different uncertain sources to obtain the values of variables of interest together with the uncertainty in these. In this work we provide a thorough discussion of the robot localization problem resolved by Kalman Filter, Adaptive Time Delay Neural Network and Support Vector machines.

Keywords—Extended Kalman Filter, Adaptive Time Delay Neural Network, Support Vector Machines, Robot, Localization

1. Introduction

The problem of robot localization consists of answering the question Where am I? from a robot’s point of view. This means the robot has to find out its location relative to the environment. When we talk about location, pose, or position we mean the x and y coordinates and heading direction of a robot in a global coordinate system. The localization problem is an important problem. It is a key component in many successful autonomous robot systems [1]. If a robot does not know where it is relative to the environment, it is difficult to decide what to do. The robot will most likely need to have at least some idea of where it is to be able to operate and act successfully [2, 3]. By some authors the robot localization problem has been stated as the most fundamental problem to providing robots truly autonomous capabilities” [4]. To be able to move around in an environment a robotic vehicle has a guidance or driving system [5]. A guidance system can consist of wheels, tracks or legs, in principle anything that makes the vehicle move around. These components are called actuators.

Obviously, the guidance system plays an important role in the physical position of a robot. The guidance system directly changes the location of the vehicle. Without a guidance system the robot is not driving around, which makes localizing itself a lot easier. Assuming that a robot does have a guidance system, the way the guidance system changes the location contains valuable information in estimating the location.

2. Kalman Filter

The Kalman filter is essentially a set of mathematical equations that implement a predictor-corrector type estimator that is optimal in the sense that it minimizes the estimated error covariance—when some presumed conditions are met.

The Kalman filter estimates a process by using a form of feedback control: the filter estimates the process state at some time and then obtains feedback in the form of (noisy) measurements. As such, the equations for the Kalman filter fall into two groups: time update equations and measurement update equations. The time update equations are responsible for projecting forward (in time) the current state and error covariance estimates to obtain the a priori estimates for the next time step. The measurement update equations are responsible for the feedback—i.e. for incorporating a new measurement into the a priori estimate to obtain an improved a posteriori estimate[6].

The time update equations can also be thought of as predictor equations, while the measurement update equations can be thought of as corrector equations. Indeed the final estimation algorithm resembles that of a predictor-corrector algorithm for solving numerical problems as shown below in Figure 1.

Figure 2: Kalman Filter operations.

Where:

- $A$ might change with each time step, and matrix $B$ relates the optional control input $u$ to the state $x$.
- $Q$ is the process noise covariance; $P_0$ is the a priori estimate error covariance.
- $K_t$ is Kalman gain, $H$ in the measurement equation relates the state to the measurement $z_t$.

I. THE EXTENDED KALMAN FILTER

The Kalman Filter above addresses the general problem of trying to estimate the state $x$ of a discrete-time controlled process that is governed by a linear equation. But if the process to be estimated and (or) the measurement relationship to the process is non-linear we have work with the extended form as in figure 3.

Figure 3: Extended Kalman Filter Operations.

Where:

- $H$, $V$ are the measurement Jacobians at step $k$, and $R_k$ is the measurement noise covariance.

II. ADAPTIVE TIME DELAY NEURAL NETWORK

The Adaptive Time Delay Neural Network takes the structure of the Multi Layer perceptron taking delay into account. Instead of taking all the neurons at the same time one takes only part of them. Each entry is delayed by an adjustable time delay like the weights of the network. One thus will sweep window of a fixed but variable size on the space of entry.

Figure 4 shows a delay block between two units $i$, $j$, and Figure 5 presents general view of an ATNN (Adaptive Time Delay Neural Network).

Figure 4: Delay Block diagram

Figure 5: Diagram of ATNN.

3. Training

A basic concept in the study and the use of networks of neurons is that of training. We indicate by this term, always in reference to biology, the procedure which consists in estimating the parameters of the various neurons of the network so, as well as possible; it fills the task which is affected.

It is supposed that the parameters of the network are updated in a discrete way and that the entries are differentiable.

The output of node is defined as follows [7]:

$$a_{j,h}(t_n) = \begin{cases} f_j \left( S_{j,h}(t_n) \right) & \text{si } h \geq 2 \\ a_{j,0}(t_n) & \text{si } h=1 \end{cases}$$

(1)

Where:

$$S_{j,h}(t_n) = \sum_{i \in N_{h-1}} \sum_{k=1}^{K_{j,h-1}} w_{j,h-1}(t_n - \tau_{j,h,k-1})$$

And $f$ is a differentiable and non-decreasing function defined as follows.
\[ f_{j,h}(x) = \frac{\beta_{j,h}}{1 + e^{-\alpha_{j,h}x}} - \gamma_{j,h} \] (3)

Where

\[ f_{j,h}(x) \text{ is in } [-\gamma_{j,h}, \beta_{j,h} - \gamma_{j,h}] \]

The modification of the weights as well as the deadlines is made by the algorithm of the gradient descent.

Where the error is defined as follows:

\[ E(t_n) = \frac{1}{2} \sum (d_j(t_n) - a_j(t_n))^2 \] (4)

Where \( N_L \) is the number of neurons in the output layer, and \( d_j(t_n) \) is the desired exit of the node \( i \) at time \( t_n \).

Time Delay are adapted as follows:

\[ \tau_{jik,h-1} = \tau_{jik,h-1} + \Delta \tau \] (5)

Such as:

\[ \Delta \tau = -\eta \frac{\partial E(t_n)}{\partial \tau_{jik,h-1}} \] (6)

The weight changes in the following way:

\[ w_{jik,h-1} = w_{jik,h-1} + \Delta w_{jik,h-1} \] (7)

Such as:

\[ \Delta w_{jik,h-1} = -\eta \frac{\partial E(t_n)}{\partial w_{jik,h-1}} \] (8)

4. Support Vector Machines

Consider the following problem: we are given a data set

\[ g = \{(x_i, y_i)\}_{i=1}^N \] obtained by sampling, with noise, some unknown function \( f(x) \) and we are asked to recover the function \( f \), or an approximation of it, that has at most \( \varepsilon \) deviation from the actually obtained targets \( y_i \) for all the training data \( g \), and at the same time is as flat as possible. In other words, we do not care about errors as long as they are less than, but will not accept any deviation larger than this [08].

A. Linear Case

We have:

\[ |y - f(x)|_\varepsilon := \max(0, |y - f(x)| - \varepsilon) \] (9)

\[ f(x) = \langle w, x \rangle + b \quad b \in \mathbb{R} \] (10)

Where \( \langle \cdot, \cdot \rangle \) denotes the dot product in the space of the input patterns. Flatness in the case of (10) means that one seeks a small \( w \). One way to ensure this is to minimize the norm. We can write this problem as a convex optimization problem [09]:

\[ \min \frac{1}{2} ||w||^2 + C \sum \xi_i^+ + \xi_i^- \] (11)

with \( \{y_i - \langle w, x_i \rangle - b \in \varepsilon \}

\[ \{\langle w, x_i \rangle + b - y_i \leq \xi_i^- \}

The tacit assumption in (10) was that such a function actually exists that approximates all pairs \((x_i, y_i)\) that the convex optimization problem is feasible.

Sometimes, however, this may not be the case, or we also may want to allow for some errors. One can introduce slack variables \( \zeta_i^- \) to cope with otherwise infeasible constraints of the optimization problem (10).

We define:

\[ \zeta_i^- = \max(0, y_i - f(x_i) - \varepsilon) \] (13)

\[ \zeta_i^+ = \max(0, y_i - f(x_i) + \varepsilon) \] (14)

\[ \zeta_i = \max(\zeta_i^+, \zeta_i^-) \] (15)

Hence we arrive at the formulation stated in [10].

\[ \min \frac{1}{2} ||w||^2 + C \sum _i (\xi_i^+ + \xi_i^-) \] (16)

with \( y_i - \langle w, x_i \rangle - b - \varepsilon \leq \xi_i^+ \)

\[ (\langle w, x_i \rangle + b) - y_i - \varepsilon \leq \xi_i^- \] (17)

The constant \( C > 0 \) determines the trade-off between the flatness of \( f \) and the amount up to which \( \varepsilon \) deviations larger than are tolerated.

In most cases the optimization problem (17) can be solved more easily in its dual formulation. Moreover, the dual formulation provides the key for extending SV machine to nonlinear functions. Hence we will use a standard dualization method utilizing Lagrange multipliers, as described [10].

Volume 17, 2020

\[ L = \frac{1}{2} \| \mathbf{w} \|^2 + C \sum_{i=1}^{N} (\zeta_i^+ + \zeta_i^-) - \sum_{i=1}^{N} \alpha_i (\epsilon + \zeta_i^+ + \zeta_i^- - y_i \langle \mathbf{w}, x_i \rangle + b) \]

\[ - \sum_{i=1}^{N} \alpha_i^* (\epsilon + \zeta_i^+ + \zeta_i^- - y_i \langle \mathbf{w}, x_i \rangle - b) - \sum_{i=1}^{N} (\eta_i^* \zeta_i^+ + \eta_i^* \zeta_i^-) \] (18)

\[ \text{avec } \alpha_i, \alpha_i^*, \eta_i, \eta_i^* \geq 0 \]

Where \( \alpha_i, \alpha_i^*, \eta_i, \eta_i^* \) are the Lagrange Multipliers.

The Lagrangian has to be minimized with respect to \( w, b \) and maximized with respect to \( \alpha \geq 0 \).

At point of optimality we have:

\[ \partial_{\mathbf{w}} L = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) = 0 \] (19)

\[ \partial_{b} L = w_{\text{opt}} - \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) x_i = 0 \] (20)

\[ \partial_{\alpha_i} L = C - \alpha_i^* - \eta_i^* = 0 \] (21)

Substituting (19, 20, and 21) in (18) we get:

\[ \max \left\{ \frac{1}{2} \sum_{i,j=1}^{N} (\alpha_i - \alpha_i^*) (\alpha_j - \alpha_j^*) \langle x_i, x_j \rangle \right\} \]

\[ - \epsilon \sum_{i=1}^{N} (\alpha_i + \alpha_i^*) + \sum_{i=1}^{N} \eta_i (\alpha_i - \alpha_i^*) \] (22)

\[ \text{avec } \left\{ \begin{array}{l}
\sum_{i=1}^{N} (\alpha_i - \alpha_i^*) = 0 \\
\alpha_i, \alpha_i^* \text{ if } 0 < C \end{array} \right\} \]

In deriving (18) we already eliminated the dual variables \( \eta_i, \eta_i^* \) through condition (21) which can be reformulated as

\[ \eta_i^* = (C - \alpha_i) \] (24)

Eq. (20) can be rewritten as follows:

\[ \mathbf{w} = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) x_i \] (25)

Thus;

\[ f(x) = \sum_{i=1}^{N} (\alpha_i - \alpha_i^*) \langle x_i, x \rangle + b \] (26)

What is called support vectors expansion i.e. \( w \) can be completely described as a linear combination of the training patterns. In a sense, the complexity of a function's representation by SVs is independent of the dimensionality of the input space, and depends only on the number of SVs.

Moreover, note that the complete algorithm can be described in terms of dot products between the data. Even when evaluating \( f(x) \) we need not compute \( w \) explicitly.

C. Computing \( b \)

\( b \) can be computed by exploiting the so called Krush-Kuhn-Tucker (KKT) conditions [12]. These state that at the point of the solution the product between dual variables and constraints has to vanish.

\[ \alpha_i (\epsilon + \zeta_i^+ + \zeta_i^- - y_i \langle \mathbf{w}, x_i \rangle + b) = 0 \] (27)

And

\[ (C - \alpha_i) \zeta_i^+ = 0 \] (28)

\[ (C - \alpha_i^*) \zeta_i^- = 0 \] (29)

For points which are apart from the band (\( \epsilon \)-insensitive tubes) have

\[ \alpha_i^* = C \] (30)

The points inside the band have

\[ \alpha_i^{(\ast)} = 0 \] (31)

The others

\[ 0 < \alpha_i^{(\ast)} < C \] (32)

The latter one has

\[ \zeta_i^* = 0 \] (33)

Consequently \( b \) calculation as follows [13]:

\[ b = y_i - \langle \mathbf{w}, x_i \rangle - \epsilon \quad \text{for } \alpha_i \in (0, C) \] (34)

\[ b = y_i - \langle \mathbf{w}, x_i \rangle + \epsilon \quad \text{pour } \alpha_i^* \in (0, C) \] (35)

From (24) it follows that only for \( |y_i f(x)| \geq \epsilon \) the Lagrange multipliers may be nonzero, or in other words, for all samples inside the \( \epsilon \)-insensitive tube (i.e. the shaded region in Fig. 1) the vanish for \( |y_i f(x)| < \epsilon \); the second factor in (27) is...
nonzero, hence \( \alpha_i^* \) has to be zero such that the KKT conditions are satisfied. Therefore we don’t need all the points to define \( w \). The examples that come with non-vanishing coefficients are called Support Vectors.

**D. Linear Case Non Linear Case**

This concept can be extended to the case when \( f \) is non-linear. A non-linear mapping which maps the input data to a high dimensional space (also called the feature space) is introduced. We can then try to find a linear function in feature space.

Thus we avoid translating the input data to feature space first and then finding their inner products.

The difference in the linear case is that \( w \) is no longer given explicitly. Also note that in the nonlinear setting, the optimization problem corresponds to finding the flattest function in feature space, not in input space [14].

**5. Experimental Results**

We consider a mobile robot with the kinematics of a unicycle. Motion is generated by two independently actuated wheels, whose rotation is measured by incremental encoders [15].

A simplified model of a mobile robot is presented in Figure 7.

**TABLE I. ATNN RESULT**

<table>
<thead>
<tr>
<th></th>
<th>Training Error</th>
<th>Test Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>ATNN</td>
<td></td>
<td></td>
</tr>
<tr>
<td>On X</td>
<td>7.97E-04</td>
<td>3.60E-02</td>
</tr>
<tr>
<td>On Y</td>
<td>4.22E-04</td>
<td>3.70E-04</td>
</tr>
<tr>
<td>On ( \phi )</td>
<td>3.10E-02</td>
<td>1.01E-04</td>
</tr>

<tr>
<td>On X</td>
<td>1.29E-01</td>
</tr>
<tr>
<td>On Y</td>
<td>4.29E-01</td>
</tr>
<tr>
<td>On ( \phi )</td>
<td>1.17E-02</td>
</tr>
</tbody>
</table>

According to Tables 1, 2 and 3 we see well that the new estimators proposed within the framework of this study gives better results which the EKF itself which is sensitive to the strong disturbances, and which at any moment requires the knowledge of all the variables defining the state of the system, on the other hand the SVM models and ATNN reach to the global minimum of the error.

We judge that SVM is the best estimator within the framework of our study.

**6. Conclusion**

As we see ATNN and SVM gave better results than EKF. The results show promise for using neural networks and SVM in estimating the states of a nonlinear system.
